Citation:

Fakharian E, Sehat Z, Sehat M, Omidi A. The Relationship Between Trauma and Socioeconomic Status in People Over 15 in Kashan, Iran: A Population-Based Study. *Journal of Social Behavior and Community Health (JSBCH)*. 2023; 7(2): 1126-1136.

ABSTRACT

Background: Today, global attention has been directed towards differences in the health of different Socioeconomy of society (SES) groups. Trauma is one of the categories where SES determinants are not well understood, especially in developing countries. This study aims to determine the annual incidence of traumabased on SES in people over 15 years old in Kashan.

Methods: This was a population-based cross-sectional study using a household survey. Data were collected through stratified-cluster sampling during 2018-2019 for over 15-year in Kashan. The researchers conducted univariate and multivariate analyses to evaluate trauma during and the past year regarding SES of individuals using Principal Components Analysis (PCA).

Results: The incidence of trauma was 70.6 (62.6-78.7) in 1000 annually, the risk of trauma in low SES was 1.06 (0.82-1.38), in moderate SES, 0.87 (0.69-1.10), and in high SES, it was 1.13 (0.84-1.52). Among different SES groups, mechanisms of injury were different (P-value = 0.09); also, the annual incidence of trauma in different SES groups was different based on the place of trauma (P-value = 0.02), the number of injuries (P-value = 0.00), treatment (P-value = 0.02), and the time to return to work (P-value = 0.00).

Conclusions: Annual incidence of trauma in different SES groups was different based on the place of trauma, the number of injuries, treatment, and time to return to work. The relationship between SES status and incidence of trauma is important to provide preventive services.

Keywords: Incidence, Epidemiology, Population-Based Study, Socioeconomic Status, Traumatic Injuries.

Introductions

Intentional or unintentional traumas have detrimental effects on individual and health budgets (Murray CJ. 2013). Trauma is a leading cause of early death, morbidity and disability, imposing a huge burden on public health in these aspects of lost years of life and social costs. The burden of trauma is not equally distributed across all groups of society and often disproportionately affects some groups, including the young and poor population (Gad MA. 2012). In recent years, global attention has been on the differences in the health of different socioeconomic status (SES) of society (Marmot M. 2007). Today, there are economic, gender, and racial differences in the field of health, throughout the world (Barreto ML. 2017). Understanding different characteristics of various classes of society to change goal setting is crucial, and health executives need to know to what extent their current or planned policies are sensitive to SES disparities to address them (Gauld R. 2012).

SES does not just encompass income but also education, occupation, and social class. SES can encompass quality of life attributes as well as the opportunities and privileges afforded to people within society. Poverty, specifically, is not the result of a single factor; it is characterized by multiple physical and psychosocial stressors (Lago S. 2018, Saif-Ur-Rahman KM. 2018).

Trauma is one of the categories where SES determinants are not well understood, especially in developing countries. Identifying high-risk SES factors for injury can provide an opportunity to implement preventive interventions in high-risk individuals (Gauld R. 2012, Lago S. 2018).

About 90% of the burden of trauma pertains to low and middle-income countries. Moreover, trauma is the most common cause of death among people in age range of 15–59 (Sehat Z. 2022).

In Europe, people living in middle or low-income countries are 3.6 times more likely to die from trauma than those living in high-income countries. There is a difference regarding all specific causes of injury (Lillini R. 2019, Zoni AC. 2016). In Iran, injuries are of higher importance;

following ischemic heart diseases (9.1%) and low back pain (9%), injuries specialty RTIs (7.3%), are considered the third major contributor to disability-adjusted life years (DALYs). Similar to the global status, in this country, injuries are the first cause of mortality among 15–49 year-old population in both genders (Hashemi E. 2018, Sadeghi-Bazargani H. 2016, Forouzanfar MH. 2014). The burden of trauma is not equally distributed among all groups of societies, and it often disproportionately affects young and poor populations (Gauld R. 2012), resulting in socioeconomic inequalities in health (Sehat Z. 2022). Remarkably, injury has also imposed a lot of direct and indirect economic and social costs on society, which has led health care policymakers to adopt key measures to identify risk factors (Perel P. 2004, Sadeghi-Bazargani H. 2012). Reducing the mortality rate and SES burden, and improving the severely injured patients are the benefits of these policies in different countries (Radjou AN. 2018). Further developments in this area require information gathering, planning, and formulation of new strategies. People's daily living conditions and SES affecting health have a decisive role in traumatic injuries and their consequences. They can be very useful in preventing trauma and its complications (Lehtola S. 2006, Reihani H. 2017). Considering the relationship and different prevalence of trauma in different socio-economic levels and even the type of trauma injuries, this study aims to describe the pattern of annual incidence of non-fatal injuries in people over 15 based on SES in Kashan, Iran.

Methods

This was a population-based cross-sectional study on individuals over 15 residing in Kashan during 2018–2019 using stratified-cluster sampling. The city of Kashan was divided into five regions based on Municipal division maps, and 25 people from each area were surveyed. All clusters of all areas were identified in the map of Kashan city and were numbered; then, the authors randomly

selected clusters between numbered areas. Twenty-five households were examined in each cluster. The researcher was randomly referred to each of the households, and in each household, randomly one person over 15 was chosen using Kish Grid tables to interview and complete the questionnaire after obtaining informed consent (Khosrozadeh H. 2015). In the absence of randomly selected person or failure to cooperate for the first time, interviews were referred to this person three times to collect information and if she/he did not cooperate, the participant was replaced with the neighboring home. Household surveys were conducted in native language of Kashan (Persian) by trained research assistants from Kashan Medical Science University.

Based on the following formula

$$n = \frac{Z_{1-\alpha/2}^2 \times p \times q}{d^2} \text{ Considering } d = 1.5,$$

Considering the prevalence of trauma at the community status, the minimum number of samples to assess the annual incidence of trauma, was 32.3%, and the required sample size for the study was $n = \frac{963}{32.2\%} = 2981$; then, this number was multiplied by 1.5 in the design effect, and a total of 3875 study samples were determined. (Saadat S. 2011, O'Donnell ML. 2013).

In order to collect the required samples, the authors referred to 4800 households: 4,200 of which agreed to interview for the study (response rate = 87.5%). one hundred and eighty cases were incomplete and unusable, and 140 of the collected data were, which were excluded from the study in the monitoring and evaluation phase. In total, 3880 households were surveyed and collected data were analyzed.

In this study, injury was defined as any intentional or unintentional physical injury following traumatic events. In addition, household was defined as a group of people living together in a dwelling with a separate outer door and a separate kitchen (Barreto, M. L. 2017).

In data gathering phase, from each subject who reported traumatic injury during the past year, the

follow-up questions were asked; they included mechanism, type, number, place, the time of traumatic injuries and hospitalization, treatment, and return to work after trauma. In this study, every participant, mental health and quality of life and disability and Post-traumatic stress disorder (PTSD) after trauma were surveyed.

The instruments used in this study were patient's information questionnaire which consisted of the following parts:

1- **Demographic variables:** age, gender, nationality, ethnicity, marital status, education, occupation, insurance, residence, duration of residence in Kashan, smoking, smoking Hookah, drug addiction, and alcohol.

2- **SES data:** To determine the economic status of individuals, Principal Components Analysis (PCA) method were used. In this method, ten home items (homeownership type, residential area, dishwasher, advanced TV, fridge freezer, microwave oven, car, computer, lipstick and internet access at home) and two cases of social factors (job and education of the head of household) were used to make new variable as asset index. Then, asset index were calculated and divided all the participants in study into three groups with high, middle and low SES (Sehat Z. 2022, Ghobad M. 2018, Garmaroudi GR. 2010, Mansouri A. 2018).

3- **Health status:** This includes the history of a specific illness, diabetes, hypertension, mental disorder, family history of a specific illness, congenital disease, medications used, surgical history, history of treatment and hospitalization, history of disabling diseases, type of health care received, and type of insurance (Sehat Z. 2022).

4- **Trauma data:** the history of trauma during the past year, cause of trauma, type of trauma, time of injury, location of the injury, number of injuries, injury treatment, hospitalization, and return to work and normal life (Mansouri A. 2018).

All the data analysis were performed using SPSS 22 and STATA 12 software. The Kolmogorov-Smirnov test was used for assessing

data normality. Chi-square and Fisher's Exact tests were used to examine differences between the two variables. Logistic regression analysis was used to examine the variables which were significantly associated with trauma outcomes. The significance level was considered less than 0.05, and univariate analysis was used to investigate the relationship between variables and trauma outcomes. Odds ratios (OR) with a 95% confidence interval were reported throughout this study.

1- Using PCA method, the new asset index was calculated on ten homeowners and two social factors and divided into three groups with high, middle, and low social status based on the mean of the variables and the three percentiles of the community. In the PCA method, 12 SES factors in the model of factors having a weighting value above 1, they are used to calculate the asset index and then the sum of SES factors based on the weighting of the first factor. Asset index is created. The higher the weighting value of a variable, the greater would be the value of that variable in society to different SES groups (Sehat Z. 2022, Ghobad M. 2018, Garmaroudi GR. 2010, Mansouri A. 2018, Love JR. 20109).

In this study, factors such as Internet access, microwave oven, residential area, laptop, car, and household education had weighed more than one

value, and overall, 71.2% of the variance of variables were covered.

This study was being approved by ethical committee of Kashan Medical Science University, Kashan, Iran (Code of Ethics (1397,094)).

Results

The Kolmogorove-Smirnov test revealed that the variables did not have a normal distribution. The association between categorical variables (such as gender and educational status) , continuous variables (such as age), and the outcome of SES was examined through chi-square and the ManneWhitney U tests, respectively.

In this study, 3880 people were studied. Based on SES factors, the subjects were divided into three groups with low, moderate, and high SES. Most of the subjects had moderate SES. Among all populations of study, incidence of trauma was 70.6 (62.6-78.7) in 1000 annually. A low incidence of trauma was observed in the high SES; in low SES, the incidence of trauma was more, and in the moderate SES, the highest rate of trauma was observed. Table 1 shows the number (%) of participants in the three SES groups and the incidence of trauma per year in each group.

Table 1. incidence of trauma among the participants over 15 with different SES

SES	Total ^a	Trauma in the past year ^b	Risk ratio	CI 95%		P-value ^c

High	816 (21%)	52 (6.4%)	1			

a N(Percent) b Chi-square test c logistic regression

In all SES groups, men and women had similar distribution; however, in the group with high SES, women showed a higher percentage of trauma than the other two groups. In all SES groups, people with injury were mostly in the age group of 30-59. In the moderate SES group, the number of people with injury aged 15 to 29 was higher than the other two groups , and in the low SES, number of

traumatized cases over 60 was more than the other groups. In all the three SES groups, the rate of married people was higher than single ones, and statistical tests showed that this relationship was significant (P-value = 0.00).

In all SES groups, the Persian race experienced the highest numbers of trauma, other races were in the low SES group.

In this study, people with low SES showed the highest rate of smoking. Furthermore, the rate of hookah smoking among the low SES group was higher than the other two groups . Drug addiction

and alcohol abuse were reported in both groups of low and moderate SES. Table 2, shows the univariate associations of SES characteristics and demographics for traumatic injury.

a Significance: P-value < 0.05

Among the three groups classified according to SES, different trauma mechanisms were more common in the moderate group. But burn injuries and family disputes were more common in people with high SES.

In all the three groups, the number of people with multiple injuries was more than those with one injury. 1 to 7 days' of hospitalization showed the highest rate of traumatic patients. In groups with different SES, the number of patients who received non-surgical treatment was more than those who underwent surgical treatment. The highest number of surgeries occurred in the

moderate group with the highest number of traumas compared to the other two groups. Chi-square test showed no significant relationship between SES and the type of treatment. The lowest and highest rates of return to work after trauma belonged to the low SES. People with a low- and moderate SES experienced the highest number of trauma incidents in the street, and as for the highest SES, most of the incidents occurred at home. The chi-square test showed a significant relationship between SES and location of injury. Table 4 shows the different variables of trauma based on SES.

a Data are presented as No. (%) b ,Chi-square test, c More than one injury

In different SES groups regarding the low SES, the highest number of traumas occurred in April and February; for the moderate group, they occurred in May and July, and for the high SES, the largest number of traumas occurred in June and January. Chi-square test showed a significant relationship between SES and the time of injury.

Discussion

This population survey suggested that the incidence of injury in Iran was higher than the estimates extracted from hospital-based studies. In contrast, this research assessed the annual incidence rates of non-fatal injuries. This was because all the injuries are not admitted to hospitals, some cases are referred to peripheral clinics, and some even do not seek medical services.

In this project, 3880 people were studied.

Among the three groups of SES, the annual incidence of trauma in the moderate SES group was higher than other groups. In addition, the frequency of injuries was higher in males than the females. But in the high SES group, women with trauma accounted for a higher percentage of people than the other two groups. Many studies in Iran and other countries (Azami-Aghdash S. 2017, Bahadori M. 2015) have mention several factors that may be applicable to most Low- and Middle-income Countries (LMICs). Males are more vulnerable to injury risks due to the special socio-cultural context (more driving, more occupational threats, violence-induced injuries and so on). But, some types of injuries such as those that occur at home may be seen more in females than males due to females' gender roles or the nature of their duties (Azami-Aghdash S. 2017, Bahadori M.

2015).

According to this study, young people were a large number of injury victims, in line with the majority of studies conducted in this area. In the middle SES, 15-29 individuals were more than the other two groups (37.4%). As stated in the results section, the largest number of people with trauma belonged to the moderate SES group, and most people with trauma were in the age group of 15 to 29. In the low-SES group, however, the percentage of people over 60 suffered from more traumatic incidences than the other groups (25%). The cause of higher rate of trauma in this age group could be to the fact that the number of people in this age group was lower.

Age has always been a matter of interest in injury research such that some age groups account for the majority of the injuries. For example, traffic injuries were reported to be the leading cause of death in 15-29 age group (Hashemi E. 2018, Nagata T. 2017). Moreover, the highest increase in the total global rate of years of life with disabilities (YLDs) were between the ages of 40 and 69 (Hashemi E. 2018, Al-Aamri AK. 2017). According to the current study, different trauma mechanisms were more common in the moderate group. In different SES groups, the timing of events were different, and the place of events was different. This pattern was similar to many previous studies (Hashemi E. 2018, Reihani H. 2017, Saadat S. 2011). Traffic accidents were the majority of injuries which was consistent with the results of most of the studies in this field (Sehat Z. 2022, Hashemi E. 2018, Reihani H. 2017). Iran had the world's highest Road Traffic Accident (RTA) death rate (Hashemi E. 2018). Despite the advances in the prevention of RTA in recent years, they were the primary cause of injuries and the second greatest cause of mortality in Iran (Bakhtiyari M. 2014, Ardalan A. 2014). Based on the results, the rate of motorcycle accidents and their injuries was higher among RTA cases, which was consistent with the numbers obtained from other studies. Also, Falls, poisonings, burns, and road traffic injuries in urban Peruvian children and

adolescents (Donroe J. 2007, Yongchaitrakul T. 2012, Hassanzadeh J. 2013).

The majority of accidents occurred on roads. Since RTAs were the main cause of injuries, roads were the primary accident scene. According to a 2013 WHO report, the safety of Iran's roads has improved slightly in the past few years (Toroyan T. 2013). But, more initiatives are needed in order to achieve a satisfactory level (Hashemi E. 2018). Poverty is associated with high risk of place of living and residences such as flood-prone and vulnerable home construction that cause prone people to be aggravated to trauma. This increased risk may become more exacerbated in the future. Analyses of the impact of global warming suggest that, worldwide, impoverished populations would be the most impacted by natural hazards associated with climate change by the year 2030 (Santiago PN. 2013, Shahbazi F. 2019).

Limitation of this study was a population-based study with many limitations. While the data were randomly collected, it might not be a complete indicator of the community. However, the data didn't completely match age and sex structure estimates of Kashan. For comparison, the researchers adjusted data based on sex and age, considering that the incidence rate of population-based study was different from a hospital base study.

Households were reluctant to report certain injuries with social implications or feared consequences of reporting events such as self-poisonings or suicidal behaviors and injuries from family violence. For this problem, before starting the interview, objectives of research were described and the subjects were assured that their information would remain confidential to the researcher.

Significant recall bias, would lead to a decreasing disability reported over time, as people would tend to remember smaller injuries that happened recently. Injured people in the nearly time later are reporting many post-traumatic disorders such as disabilities and stress less than far months ago. To overcome this problem,

standard test in this study was used.

Conclusion

In this study, being a 15-29 male employed, and identified as Persian, were characteristics associated with a higher risk for non-fatal injury. Individuals' SES data should be considered in combination with area-level and country-level data when developing evidence-based public health policies.

One of the goals of a healthy society is eliminating differences in service delivery across different groups of people, such as differences in gender, ethnicity, race, education, income, disability, and geographic location. But, despite the commitment of governments and health systems to improve health indicators, there is still a significant difference in the health status of different social groups. The relationship between SES differences and the consequences of trauma are important for all countries, and understanding the determinants of these differences can help provide preventive services.

Acknowledgments

The authors would like to thank the Trauma Research Center of Kashan University of Medical Sciences and the students and faculty at the University for their support and assistance with this project.

Conflicts of interest

The authors declared no conflict of interest.

Funding

This study was from a Ph.D. dissertation and supported by a grant from the Kashan Medical science university Foundation.

Ethical Considerations

This study was being approved by ethical committee of Kashan Medical Science University, Kashan, Iran.

Code of Ethics

Code of Ethics of this study is 1397, 094.

Authors' contributions

Z. S, M. S, E. F, and A. O, designed the study;

Z. S and M. S, managed data collection; Z. S, analyzed data, composed the draft, edited the final manuscript, performed the literature search, and helped with the draft; M. S, assisted in data collection, analysis, drafting, and editing the draft. All the four authors read and approved of the final manuscript.

Open Access Policy

JSBCH does not charge readers and their institution for access to its papers. Full text download of all new and archived papers are free of charge.
